Received March 5, 1992

ABSTRACT

A detached tiller culture procedure was investigated as an alternative method for cereal haploid production through sexual crossing of some Triticeae with maize (*Zea mays* L.). Polyhaploid embryo recovery frequencies for seventeen *Triticum aestivum* L. (n = 3x = 21, ABD) cultivars, five *Triticum turgidum* L. (n = 2x = 14, AB) cultivars and five synthetic hexaploids of *Triticum turgidum x Aegilops squarrosa* L. (n = 3x = 21, ABD) averaged 15.6, 16.9 and 19.8%, respectively. Colchicine doubling frequencies of polyhaploids produced for *T. aestivum*, *T. turgidum* and the synthetic hexaploids were 60.7, 69.5 and 63.6%, respectively. There was low chromosome pairing at metaphase I in polyhaploids of several *T. aestivum* cultivars and in those derived from the *T. turgidum x Ae. squarrosa* synthetics. The mean metaphase I chromosomal associations of *T. aestivum* polyhaploids were 18.5 univalents + 0.03 ring bivalents + 1.13 rod bivalents + 0.08 trivalents (chiasmata = 1.34/cell), while those for polyhaploids from synthetic hexaploids were 20.1 univalents + 0.44 rod bivalents (chiasmata = 0.44/cell). The use of the maize system for haploid production in the Triticeae is very encouraging since stringent genotype specificity is not apparent. Reaching homozygosity in earlier generations will accelerate breeding progress.

Key words: Allosyndetic pairing, Chromosome doubling, Chromosome elimination, Synthetic hexaploids, *Triticum*, Wheat x maize hybridization.

INTRODUCTION

Haploid production of the Triticeae cereals has mostly relied on anther culture and sexual crossing with *Hordeum bulbosum* L. Limitations to these haploid production strategies include aneuploidy, somaclonal variation and genotypic specificity in the former approach (for review see PICARD, 1989), with the homoeologous group 5 crossability loci (*Kr1*, *Kr2*, *Kr3*) being the essential limiting factor in the latter method (SNAPE *et al.*, 1979; FALK and KASHA, 1981, 1983; SITCH and SNAPE, 1986, 1987; MUJEEB-KAZI and ASIEDU, 1990). In order to avoid tissue culture associated somaclonal variation, a sexual route to haploid production is seemingly more desirable. Recently, crosses of wheat and other members of the Triticeae with maize have been suggested as an alternative sexual route for haploid production (LAURIE and BENNETT, 1986, 1988a, 1988b; O'DONOUGHUE and BENNETT, 1988; LAURIE *et al.*,1990). Since maize appears to be insensitive to the *Kr* crossability alleles of wheat (LAURIE and BENNETT, 1987), polyhaploids can be recovered across different genotypes (SUENAGA and NAKAJIMA, 1989; INAGAKI and TAHIR, 1990), thus making it potentially superior to the *H. bulbosum* system. In addition, gametoclonal variation induced in doubled haploid lines using the maize system was similar to that found in doubled haploids obtained from wheat x *H. bulbosum* L. crosses (LAURIE and SNAPE, 1990).

The use of 2,4-D in promoting seed set and embryo formation in wheat x maize crosses is critical (INAGAKI and TAHIR, 1990). The 2,4-D treatment techniques include floret culture (LAURIE and BENNETT, 1988b), tiller injection (SUENAGA and NAKAJIMA, 1989; INAGAKI and TAHIR, 1990), spike sprays (RINES *et al.*, 1990) and floret treatment (RIERA-LIZARAZU and MUJEEB-KAZI, 1990). The use of detached spikes (RIERA-LIZARAZU and MUJEEB-KAZI, 1990) and detached spikelets (LAURIE and BENNETT, 1988b) offer more experimental flexibility because

experimental material can be transferred to locations where environmental conditions can be monitored and controlled.

High frequency of wheat polyhaploid recovery was reported for crosses between the wheat cultivar Morocco and the maize population "Pool 9A" (RIERA-LIZARAZU and MUJEEB-KAZI, 1990). In this paper we report successful polyhaploid embryo production of additional *Triticum aestivum* and *T. turgidum* L. cultivars, and of a few *T. turgidum x Aegilops squarrosa* L. synthetic hexaploids using a detached tiller culture method. Cytological and biochemical features of these polyhaploids and their doubled progeny are also characterized.

MATERIALS AND METHODS

Plant material

Field grown plants of breadwheat (*Triticum aestivum*), durum wheat (*T. turgidum*), rye (*Secale cereale*), *T. turgidum x Aegilops squarrosa* amphiploids and maize (*Zea mays*) grown at El Batan, CIMMYT, Mexico, were used (Table 1). A bulk sample of pollen from several maize cross-pollinating populations was used for all crosses.

Crossing procedures, detached tiller culture, and embryo rescue

Spikes were hand emasculated before anthesis and covered with glycine bags. When the stigmatic surface was receptive (3 to 4 d after emasculation), the spikes were pollinated with fresh maize pollen. Tillers of pollinated spikes were detached 5 cm below the peduncular node and placed in a beaker with an aqueous solution of 100 mg/l 2,4-D for transport from the field. Culms of detached tillers were then surface-sterilized in a 20% (v/v) chlorine bleach (5.25% sodium hypochlorite) solution for 5 min, rinsed six times in sterile deionized water and transferred to test tubes (45 ml) containing liquid MURASHIGE and SKOOG's (1962) basal medium components with 100 mg/l 2,4-D without agar. The test tubes with detached tillers were placed in a styrofoam box containing ice-water in the greenhouse under regimes of 25/12°C (day/night), 16 h photoperiod, and 45 to 60% relative humidity. Detached tillers remained in 2,4-D containing medium for 48 h and were then transferred to growth regulator-free medium where they remained for 12 days. The embryo rescue, plant regeneration and transplantation procedures were described earlier (MUJEEB-KAZI *et al.*, 1987).

Cytology

Somatic cytology of all regenerated plants was conducted according to the method of MUJEEB-KAZI and MIRANDA (1985). For meiotic analysis young spikes were fixed in 6:3:1 (ethanol (99%):chloroform: glacial acetic acid) for 48 h and stored in 70% ethanol in the freezer (−10°C) until use. Anthers at metaphase I were stained in alcoholic carmine (SNOW, 1963), then processed according to the modified procedure of MUJEEB-KAZI *et al.* (1992) for high contrast, intense staining and reduced stickiness. Mean metaphase I pairing associations were calculated from 25 meiocytes for some of the bread wheat and synthetic hexaploid polyhaploids.

Colchicine treatment

Cytologically identified polyhaploid plants were treated with colchicine as described by MUJEEB-KAZI *et al.* (1987). Successful chromosome doubling was inferred from seed setting on the colchicine-treated polyhaploid plants.

Protein separation

Some female wheat parents and their doubled haploid progenies were analyzed by studying the banding profiles of seed storage proteins and isozymes. The storage protein glutenin, and isozymes of esterase (est., E.C. 3.1.1.1) and β-amylase (α-1,4-glucan maltohydrolase, E.C. 3.2.1.2) were evaluated. Endosperm halves of mature kernels were used for protein separation and isozyme analysis.

High molecular weight glutenin subunits were separated using SDS-Polyacrylamide gel electrophoresis as described by NG *et al.* (1988) with slight modifications. Stacking gels of 2 cm and 10% separation gels of 15.5 cm were used. Thickness and width of the gels were 0.15 cm and 16 cm, respectively. Each gel was run at 20 mA constant current for 1 h followed by 30 mA constant current for 4 h on a Bio-rad Protean II electrophoresis unit. The temperature was maintained at 15°C during electrophoresis. Esterase and β-amylase isozymes were separated by isoelectric focusing using precast Pharmacia PAG plates with pH gradients of 3.5-9.5 for esterase and 4.0-6.5 for β-amylase. The running conditions and the staining protocols were described by WILLIAM and MUJEEB-KAZI (1992).

RESULTS AND DISCUSSION

Sexual crossing between members of the Triticeae and maize offers a new alternate route to haploid production (LAURIE and BENNETT, 1986, 1987, 1988a, 1988b; O'DONOUGHUE and BENNETT, 1988; LAURIE *et al.*, 1990). This avoids somaclonal variation induced aneuploidy plus genotypic specificity associated with anther culture and the *H. bulbosum* system (for review see PICARD, 1989).

Caryopses produced from crosses between the Triticeae species and maize, when harvested at 14 days post pollination, lacked normal endosperms.

Embryos floated inside the seeds in a watery solution. Generally, any embryo recovered from a caryopsis lacking normal solid endosperm is a haploid, thus serving as a morphological diagnostic for screening selfed-versus cross-pollinated products.

As reported by others (INAGAKI and TAHIR, 1990; LAURIE and REYMONDIE, 1991) we also recovered haploid embryos from many different wheat genotypes following pollinations with maize. In addition, our results obtained by using detached tillers indicate that the use of the maize system can be extended to recover polyhaploids in durum wheats and *T. turgidum x Ae. squarrosa* amphiploids (Table 1).

There was a wide range of embryo recovery frequencies in this experiment among hexaploid wheats, tetraploid wheats and the *T. turgidum x Ae. squarrosa* synthetic hexaploids with recovery averages of 15.6, 16.9, and 19.8%, respectively (Table 1). Since the earlier documentation (LAURIE and BENNETT, 1987) that wheat x maize crossing success was independent of the *Kr* locus and maize pollen donor source, we did not design this study for further establishing significant differences among genotypes. The focus was essentially upon assessing the magnitude of haploid induction amongst our genotypes for applications in wheat breeding and cytogenetics. No embryos were recovered from *S. cereale* x maize crosses. Mean plant regeneration frequencies calculated as a percentage of embryos recovered for bread wheats, durum wheats and *T. turgidum x Ae. squarrosa* amphiploids were 68.5, 73.9 and 74.5%, respectively. Successful chromosome doubling (Fig. 1) of polyhaploid plants treated with colchicine averaged

60.7% for *T. aestivum* cultivars, 69.5% for *T. turgidum* cultivars and 63.6% for the synthetic hexaploids (Table 1).

Haploid plant production frequencies of 1 to 4% have been considered acceptable for the efficient production of haploids (COMEAU *et al.*, 1988). Our average doubled haploid plant recovery frequencies for *T. aestivum*, *T. turgidum* and the synthetic hexaploids ranged from 63.6 to 69.5%, average embryo excision frequencies were 15.6 to 19.8%, and the mean plant regeneration frequency range was 68.5 to 74.5% (Table 1). Though the wheat polyhaploid plant production frequencies obtained in this study more than adequately meet the economical threshold level (COMEAU *et al.*, 1988), higher frequencies across genotypes have been reported (SUENAGA and NAKAJIMA, 1989; INAGAKI and TAHIR, 1990; RIERA-LIZARAZU and MUJEEB-KAZI, 1990). The low haploid embryo recovery frequencies in this study as compared with earlier findings of RIERA-LIZARAZU and MUJEEB-KAZI (1990) are attributed to problems inherent to the detached tiller culture system. These constraints include the impossibility of total tiller sterilization, since samples were collected from the field at a time when disease factors and continuous rainfall had set in. This sterilization constraint resulted in progressive tiller culm base decay in the culture medium, thus affecting normal nutrient translocation and seed development. For such situations it may be appropriate to use intact spikes (SUENAGA and NAKAJIMA, 1989) or modify the detached tiller process. For the latter, the use of sulfurous acid to suppress contamination in culture solution and culm decay as reported by KATO *et al.* (1990) may be an alternative. Additionally, it may help to use less humid environments in controlled greenhouse crossing and to use stored maize pollen to facilitate crossing in preferred environments.

The detached tiller culture system was specifically designed for the study of nutrient translocation and seed development physiology in wheat spikes (JENNER, 1970; DONOVAN and LEE, 1977; SINGH and JENNER, 1983); hence, modifications of this technique may be needed for wider application to other species. For example, severe culm decay was observed when detached tillers of *Secale cereale* cv. Prolific and Sardev were used and no embryos were recovered in these rye x maize crosses, although LAURIE *et al.* (1989) have reported embryo initiation in rye x maize hybridizations. It appears that with rye an *in vivo* approach may be preferable. If the detached tiller method is to be commonly used, then the constitution of the nutrient solution, point of tiller detachment, plus the constraints expressed earlier must be addressed.

Cytologically analyzed plants possessed the expected haploid complement of 21 chromosomes for *T. aestivum* (Fig. 2b) and 14 chromosomes for *T. turgidum* (Fig. 3b), where each wheat parent had the euploid number of $2n = 6x = 42$ (Fig. 2a) or $2n = 4x = 28$ (fig. 3a). Two *T. aestivum* polyhaploids were aneuploids with 20 chromosomes (Fig. 3c), one of which died in the seedling stage. Another anomaly was a *T. aestivum* polyhaploid with 21 chromosomes (Fig. 3d) including a telocentric.

Polyhaploids of *T. aestivum* cultivars and the synthetic hexaploid showed very low allosyndetic pairing (Table 2 and Fig. 4). Ring bivalents were rare with chiasmata ranging from 0.44 to 1.96 per meiocyte (Table 2).

The earlier reported wheat polyhaploid ($n = 3x = 21$) meiotic associations were 18.05 univalents + 1.38 bivalents + 0.07 trivalents (RILEY and CHAPMAN, 1958). Subsequently, KIMBER and RILEY (1963) reported for bread wheat a mean frequency of 19.18 univalents + 0.90 bivalents + 0.008 trivalents from analyses of eight euhaploids; values indicating very low allosyndetic pairing. This degree of chromosome pairing is consistent with our data where the *T. aestivum* polyhaploids of several cultivars had a mean metaphase I chromosome association frequency of 18.6 univalents + 0.01 ring bivalents + 1.24 rod bivalents + 0.06 trivalents (extracted from Table 2). Values for the synthetic (*T. turgidum x Ae. squarrosa*) polyhaploid were 20.1 univalents + 0.44 bivalents. This low pairing indicates that the wheat cultivars and the synthetic hexaploid used had the dominant *Ph* locus that restricts homoeologous pairing and that the locus remained intact over the haploid induction process. Recently in *T. aestivum Ph1* euhaploids derived from wheat x barley hybrids, JAUHAR *et al.* (1991) also observed very low chromosomal pairing. Only 6.5 to 11.0% of the complement paired homoeologously with 0.7 to 1.2 chiasmata per cell.

Genes for high molecular weight glutenins have been located on the long arms of homoeologous group 1 chromosomes (PAYNE and LAWRENCE, 1983); grain esterase genes are on the long arms of homoeologous group 3 chromosomes (AINSWORTH *et al.*, 1984) and those for β-amylase on group 4 and 5 chromosomes (AINSWORTH *et al.*, 1983). Extensive

allelic variations have also been reported for all three systems.

Banding profiles of high molecular weight glutenins, and isozymes of seed esterase and β-amylase are shown in Figs. 5 to 7. Extensive variations in the banding profiles were observed for all three systems among the different parental lines used in this study, probably as a consequence of allelic variation. Banding profiles of high molecular weight glutenin and esterase in the doubled haploid progenies were identical to those present in their respective parents. For β-amylase there were some minor differences in the banding profiles within some families (Fig. 7). This isozyme variation may be partially attributed to post translational modifications (AINSWORTH *et al.*, 1983), whereas some of the band intensity differences may also be accounted for by the endosperm protein concentration variation. In general, the close similarity in the banding profiles of the doubled haploid progenies and their parents suggests stable transmission of genetic information by this procedure of doubled haploid production. It also indicates that the parental genetic information for the enzyme systems evaluated is fixed in the doubled haploid progeny without alteration.

The use of the maize system for haploid production in the Triticeae is very encouraging since stringent genotype specificity is not apparent. Reaching homozygosity in earlier generations will accelerate cereal breeding progress. Recent results (INAGAKI and TAHIR, 1990; LAURIE and REYMONDIE, 1991) corroborate this contention where high frequency haploid production has been reported in spring and winter wheat x maize crosses. Despite the current, presumably location specific, contamination problem with the detached tiller procedure encountered in this study, the potential for its application in haploid production research in cereals is promising. More durum wheat and rye genotypes need to be tested to further evaluate the detached tiller procedure for haploid production using sexual crossing with maize.

JOURNAL OF

GENETICS & BREEDING

INSTRUCTIONS TO CONTRIBUTORS

1. GENERAL

Journal of Genetics & Breeding (J.G&B) is an international journal which will consider for publication original papers written in English. For reviews the Editors must be contacted in advance.
Submission of a manuscript implies that it has not been published before and it is not under consideration for publication elsewhere.
The manuscript will be reviewed for a decision on acceptance, revision or rejection in six to seven weeks. Failure to follow the instructions below may lead to a delay in publication or rejection of the paper.

2. SPECIFIC INSTRUCTIONS

Papers must be typed double spaced on one side only and sent in duplicate to the nearest Editor.
THE FIRST PAGE must include the title, name(s) and permanent address(es) of the author(s), the name, address and telefax number, if available, of the author to whom all correspondance should be sent.
THE SECOND PAGE must include abstract, key words, footnotes, abbreviations and symbols in alphabetical order.
THE ABSTRACT must be clear and concise with a maximum of 200 words; it must not contain citations.
KEY WORDS (not more than six) are words *not* already in the title.
THE INTRODUCTION should contain information to provide the background for the paper; the objectives of the paper should be stated clearly in this section. Text references should be as follows:

a) KRAUSE and WEIS (1984) or GOVINDJEE *et al.* (1981) if more than two authors;
b) (KRAUSE and WEIS, 1984; SIVAK *et al.*, 1985) - chronologically.

THE RESULTS should present the experimental findings concisely.
THE DISCUSSION should be a critical evaluation of data and should not reiterate material in the Results section. The Results and Discussion sections may be combined for conciseness.
ACKNOWLEDGMENTS must be as brief as possible.
THE REFERENCES must include only publications cited in the text. They must be listed in alphabetical order under the first author's name, listing all authors and the complete title according the following examples:
a) Journal Articles:
VERTUCCI, C.W., ELLENSON, J.L. and LEOPOLD, A.C., 1985. Chlorophyll fluorescence characteristics associated with hydration level in pea cotyledons. *Plant Physiol.* 79: 248-252.
b) Book Articles:
BENNET M.D., 1982. The nucleotypic basis of the spatial ordering of chromosomes in eukaryotes and the implications of the order for genome evolution and phenotypic variation. In: G.A. DOVER and R.B. FLAVELL eds., *Genome Evolution,* Academic Press, London, pp. 41-66.
FOR ABBREVIATIONS of journal titles, authors must follow the rules of *World List of Scientific Periodicals* or BIOSIS *List of Serials.* Names of periodical not listed there must be written out in full. Unpublished data, articles in preparation and personal communications must not be listed in "References" but must be referred to parenthetically in the text. Articles "in press" must be so designated, the journals in which the articles will appear being included in the "References". For abbreviations of chemical names authors should consult the directions given in "*Chemical Abstract*". The metric system is standard and SI units should be used.
GENUS and SPECIES NAMES, journal titles and words to be printed in *italics* must be underlined singly.
TABLES and FIGURES (photographs and drawings) must be numbered consecutively in Arabic numerals with the author's names on the back. Each table and figure must be placed on a separate page. Tables must have a short legend describing the general meaning of the table. Footnotes to tables must be indicated by lower-case superscript letters, beginning with[a].
Figures must be provided with concise, descriptive legends at the end of the typescript. Drawings should be at least twice as large as the printed size. Photographs must be furnished as good quality glossy positive prints of a size permitting direct printing. Authors should choose a proper scale so that each figure or group of figures can be fitted into a maximum final width of either 8.8 cm or 18.2 cm. Arrows, letters, number and other symbols must be inserted with template rub-on letters; otherwise, inscriptions must be made on trasparent overlay. The desidered position of tables and figures should be marked in the margin of the manuscript. Two sets of the original photographs and one set of the original drawings are required.
SHORT COMMUNICATIONS. These are intended as preliminary reports of important findings. Research results that are complete but characterized by a rather limited scope of investigation as well as descriptions of new techniques can be submitted as *short communications.* Usually they should contain not more than 2000 words, ten references and two tables or figures. Abstract is obligatory but the paper should not be split into sections. Other instructions for preparation are as for conventional papers.
NEWSLETTER. Information here is in the form of short technical notes, new ideas, description of research activities and updating of gene nomenclature. For contributions the Editor must be contacted in advance.

3. PROCESSING OF MANUSCRIPT

The manuscript will be sent by the Editor to the reviewers who suggest improvements and recommends accepting or declining the paper. The critiques of the reviewers with a decision letter by the Editor will be sent to the corresponding author in six to seven weeks.
A revised manuscript must be received within 6 weeks of the date of the provisional acceptance. After final acceptance the authors will receive the page proofs for perusal. Corrections are limited to typographical errors. In the interest of rapid publication the corrected proofs should be returned within 5 days by air mail. In case of delay the proofs will be corrected by the editorial staff. The paper will be published in two to three months after final acceptance.

4. OFFPRINTS

For each paper thirty (30) offprints are provided free of charge; additional offprints may be ordered at extra cost when the proofs are returned. Manuscripts will not be returned to the authors.

SUBSCRIPTION orders should be addressed to: "Journal of Genetics & Breeding", Experimental Institute for Cereal Research, Via Cassia 176, I-00191 Rome, Italy
